Abstract

This paper tries to calculate quality of life (QOL) from subjective health evaluations in Japan following Cutler and Richardson (1997) and Groot (2000). It then extends the model in several ways. Firstly, while previous studies define the domain of QOL in an ad hoc manner, i.e. excluding "excellent" or "very poor" respondents, this paper suggests a more rigorous alternative measure. Secondly, heterogeneity among individuals that is inevitable in micro-data is accounted for in the estimation process. Thirdly, economic variables such as income or job status that are considered to affect subjective health status are also accounted for. The estimation results show the following: using the same model as previous work, similar tendencies are found, but coefficients are smaller for many symptoms and diseases. Economic variables help to clarify the effect of symptoms or diseases on subjective health evaluation. The QOL measures defined in this paper are smaller for most symptoms and diseases, and thus the measures in previous research are likely to overestimate of damage to QOL by symptoms and diseases and may be inappropriate.

1 Introduction

Cost effectiveness analysis has been widely used in evaluation of new medical technology and in analysis of health policy. Though QALYs, DALYs and other methods are used to measure outcomes, each method has issues to be clarified. The Rating Scale, the Standard Gamble and the Time Trade-Off are the most widely used methods [1].

In the Rating Scale approach, there are several ways to ask subjects to describe preferences. The scale can have numbers, categories, or a ten-centimetre line on a page. Health states are placed between two clearly defined endpoints on a line. The most preferred health state is placed at one end and the least preferred at the other end. Though this method is relatively easy for subjects to understand, it is subject to measurement biases.

The Standard Gamble measure asks for preference under uncertainty. Alternative 1 is a treatment for a given health state with two possible outcomes: to live healthily for an additional t years with probability p , and to die immediately with probability $(1 - p)$. Alternative 2 is to live an additional t years with the given state. Probability p is varied until the respondent feels indifferent between two alternatives, and the preference score for the health state is p . This is based on the fundamental axioms of utility theory of Von Neumann and Morgenstern and although theoretically justified, it is complicated for general population to comprehend.

The Time Trade-Off method asks subjects to select from two alternatives. One is to live with state i for t years followed by death, and the other is to live healthily for x years (where $x < t$) followed by death. x is varied until the respondent is indifferent between two alternatives. The preference for state i is x/t . This also has some minor difficulties [2,3].

When the focus of analysis is a whole society or other aggregate, for both technical and cost considerations it is no longer possible to ask such complex questions. Subjective health status analysis is an efficient approach, but several issues remain. As the answer is subjective, comparability among different individuals is problematic, i.e. it is impossible

to sum up across a whole society. Fortunately, surveys of this kind have been performed over a long period, and some knowledge about bias by age and sex has been collected [3-6].

What is of more concern in evaluation of disease-related cost and medicine is adaptation to illness. The longer a person suffers from a disease, the smaller is the loss caused by the disease likely to be recognized. This tendency is not specific to this kind of model, and is also observed in QOL evaluations involving the difference among people with and without a disease [7].

In this paper, we try to calculate QOL from subjective health evaluation in Japan following Cutler and Richardson [3] and Groot [4], and then extend the model in several ways. Firstly, while previous studies define the domain of QOL in an ad hoc manner, i.e. excluding "excellent" or "very poor" respondents, this paper suggests a more rigorous alternative measure. Secondly, heterogeneity among individuals, inevitable in micro-data, is accounted for in the estimation process. Thirdly, economic variables such as income or job status are used as variables.

This paper is organized as follows. In the next section, the data used in this paper are explained, and then the proposed estimation models are shown in Section 3. The QOL definition is shown in Section 4, and in Sections 5 and 6 the results of the estimation of QOL are shown.

2 Data

A Living Standard Survey has been conducted every three years since 1986. The purpose of the survey is to investigate health, medical services, pensions, welfare, incomes and other factors affecting living standards. Questionnaires consist of four parts - family, individual, income and saving components. The number of subjects in the family and individual parts is approximately 780,000 individuals (280,000 families), selected randomly, and that of the income and saving surveys is approximately 120,000 individuals (40,000 families), also

selected randomly. The data used in this study were collected in 1998.

Subjective health responses range from excellent to good, fair, poor and very poor. In previous studies, respondents were asked to evaluate their health in comparison with their age peers. Note that in Cutler and Richardson [23], subjective health is measured in the opposite order.

Symptoms and diseases are surveyed in more detail than in other studies. Symptoms are fever, fatigue, sleeplessness, irritation, failing memory, headache, dizziness, bleary eyes, difficulty in seeing, tinnitus, difficulty in hearing, palpitation, difficulty in breathing, chest pain, coughs and sputum expectoration, the sniffles, noisy breathing, retching, diarrhoea, constipation, appetite lost, stomach ache, haemorrhoids, toothache, dental problems, difficulty in chewing, rash, itching, stiff shoulder, back pain, arthralgia, impairments of hands and feet, numbness, frigid hands and feet, foot edema, disuria, frequent urination, incontinence, paramenia/merorrhagia, broken bones and sprain, wounds, and other symptoms. The respondents mark the symptoms multiply, but the survey does not have information about whether they have considered seeing a doctor, or the seriousness of the symptoms.

Diseases they suffer from and are consulting a doctor about are diabetes, obesity, hyperlipidaemia, diseases of thyroid gland, dementia, psychosis, neurosis, autonomic imbalance, cataracts, retinopathy, tympanitis, deafness, hypertension, stroke, angina/AMI, other circulatory problems, acute nasopharyngitis, allergic rhinitis, asthma, other respiratory problems, gastritis/duodenitis, gastric/duodenal ulcer, hepatitis/cirrhosis, cholelithiasis/cholecystitis, other digestive problems, tooth decay, oral problems, atopic dermatitis, contact dermatitis, urticaria, boldness, gout, chronic rheumatoid arthritis, arthritis, stiff shoulder, lumbago, osteoporosis, kidney problems, prostatic hypertrophy, pre-menopausal or post-menopausal problems, fractures, injuries and burns, anaemia/haemopathy, malignant neoplasm, pregnancy, and others. The respondents also mark the symptoms multiply, and they choose the one that is of most concern.

3 Models for estimation

The basic models following previous studies are as follows. The dependent variable H_i is defined to be 1 when the i th individual assesses his or her health to be excellent, 2 good, 3 fair, 4 poor and 5 very poor. The independent variables are as follows. The vector X_i represents demographic characteristics. D_i defines diseases they suffer and S_i indicates their symptoms. The estimation method is the ordered probit method with

$$\begin{aligned}
 H_i^* &= \alpha_0 + X_i\alpha_X + D_i\alpha_D + S_i\alpha_S + \varepsilon_i \\
 H_i &= \begin{cases} 1 & \text{if } H_i^* < 0 \\ 2 & \text{if } H_i^* > 0 \text{ \& } H_i^* < C_2 \\ 3 & \text{if } H_i^* > C_2 \text{ \& } H_i^* < C_3 \\ 4 & \text{if } H_i^* > C_3 \text{ \& } H_i^* < C_4 \\ 5 & \text{if } H_i^* > C_4 \end{cases} \quad (1)
 \end{aligned}$$

where C_1 , the threshold between $H_i = 0$ and $H_i = 1$, is normalized to be 0.

Groot [4] extended the ordered probit model to explain the change in the threshold of subjective health according to these conditions:

$$\begin{aligned}
 H_i^* &= \alpha_0 + X_i\alpha_X + D_i\alpha_D + S_i\alpha_S + \varepsilon_i \\
 H_i &= \begin{cases} 1 & \text{if } H_i^* < 0 \\ 2 & \text{if } H_i^* > 0 \text{ \& } H_i^* < \beta_0^2 + X_i\beta_X^2 + D_i\beta_D^2 + S_i\beta_S^2 \\ 3 & \text{if } H_i^* > \beta_0^2 + X_i\beta_X^2 + D_i\beta_D^2 + S_i\beta_S^2 \text{ \& } H_i^* < \beta_0^3 + X_i\beta_X^3 + D_i\beta_D^3 + S_i\beta_S^3 \\ 4 & \text{if } H_i^* > \beta_0^3 + X_i\beta_X^3 + D_i\beta_D^3 + S_i\beta_S^3 \text{ \& } H_i^* < \beta_0^4 + X_i\beta_X^4 + D_i\beta_D^4 + S_i\beta_S^4 \\ 5 & \text{if } H_i^* > \beta_0^4 + X_i\beta_X^4 + D_i\beta_D^4 + S_i\beta_S^4 \end{cases} \quad (2)
 \end{aligned}$$

Hereafter, eq. (1) is called the constant threshold model and eq. (2) the function threshold model.

In the following, the economic variables E_i are used in the estimation as an alternative specification. Then all the coefficients are estimated by a heterogeneity consistent estimation method, which is appropriate for micro-data such as that used here.

4 QOL Definition

In previous studies, the effect of the j disease on QOL is defined in the constant threshold model as

$$QOL_{CR,G}^c = -\frac{\hat{\alpha}_D^j}{\hat{C}_4} \quad (3)$$

where $\hat{\cdot}$ indicates estimation and α_D^j is the coefficient of the j th disease dummy. So as to avoid unnecessary complexity, $\alpha_D^j > 0$ is assumed. In the function threshold model, QOL is defined by

$$QOL_{CR,G}^f = 1 + \frac{Z_i \hat{\alpha}_Z}{Z_i \hat{\beta}_Z^4} - \frac{Z_i \hat{\alpha}_Z + \hat{\alpha}_D^j}{Z_i \hat{\beta}_Z^4 + \hat{\beta}_D^{4j}} = 1 - \frac{Z_i \hat{\beta}_Z^4 \hat{\alpha}_D^j - Z_i \hat{\alpha}_Z \hat{\beta}_D^{4j}}{Z_i \hat{\beta}_Z^4 (Z_i \hat{\beta}_Z^4 + \hat{\beta}_D^{4j})} \quad (4)$$

Formulations of this kind are easy to understand, but there are some problems. Firstly, the domain of QOL is set in an ad hoc manner, i.e. excluding "excellent" or "very poor" respondents. Originally the QOL concept requires 0 to represent dead and 1 to represent perfect health. Thus all the respondents should be less than 1 and greater than 0. However, the previous studies assign 1 to "excellent" and 0 to "very poor". This is inconsistent with the QOL concept and QOL may thereby be overestimated.

Secondly, the denominator may be very small in comparison with the numerator, and thus the QOL measure cannot be limited to $[0, 1]$, but it is obviously defined over $[-\infty, \infty]$. Thirdly, in the constant threshold model, the QOL effect of a disease is assumed to be the same across respondents. However, there is no evidence for this and it seems to be more natural to consider QOL to be dependent upon the health status of the respondent. For example, the effect of flu is different between healthy people and ill elderly people.

To overcome such shortcomings, a new definition of QOL is proposed in this paper as

$$QOL_{HO} = \Phi(Z_i \hat{\alpha}_Z) - \Phi(Z_i \hat{\alpha}_Z + \hat{\alpha}_D^j) \quad (5)$$

where Φ is the cumulative distribution function of the standard normal distribution. This is favoured more when comparing to $QOL_{CR,G}^c$ and $QOL_{CR,G}^f$ on several counts. Firstly, QOL_{HO} defines all the respondents without excluding "excellent" and "very poor". Secondly, QOL_{HO} is always below 1 and positive. Thirdly, QOL differs among respondents even in the constant threshold model according to their health status. Fourthly, QOL is evaluated according to the true distribution of QOL_{HO} unlike $QOL_{CR,G}^c$ and $QOL_{CR,G}^f$. QOL_{HO} which is thought to have damaging or negative effects through certain symptoms or diseases on the QOL.

The term QOL_{HO} is a marginal effect of the dummy variables in the probit model. $QOL_{CR,G}^c$ and $QOL_{CR,G}^f$ defines QOL between $[-\infty, \infty]$ and causes the problem mentioned above.

Since QOL_{HO} varies among individuals, the social or aggregate QOL is

$$\int [\Phi(Z_i \hat{\alpha}_Z) - \Phi(Z_i \hat{\alpha}_Z + \hat{\alpha}_D^j)] f(di) \quad (6)$$

where $f(\cdot)$ represents the probability distribution function of individuals in this society.

5 Estimation Results

5.1 Check for Goodness of Fit

We first need to check the goodness-of-fit before evaluating the results. For the ordered probit, especially the function threshold model, it is not obvious how to evaluate goodness-of-fit. In this paper, following Kenkel [4], the estimated distribution of the subjective health evaluation will be compared with the actual distribution for the purposes of verification. While the percentages in the distribution in the actual observation show 5.44%, 13.22%, 43.94%, 32.87% and 4.51% for "excellent" to "very poor" respectively, the estimated ones in the constant threshold model for all symptoms and sicknesses are 5.49%, 13.25%, 44.09%, 32.52% and 4.62%, and in the function threshold model they are 5.50%, 13.44%, 43.87%,

32.52% and 4.65%. Therefore, both are very similar and fit well. As in the other estimated model with the economic variables and the restrictive model, the results are almost the same, so that checking for goodness-of-fit is omitted so as to save space.

5.2 Constant Threshold Model

In Table 2, age is seen not to be significant, and that females evaluate their health significantly worse than males do, which is the same result as in the UK. The number of children makes their health evaluation better, a result opposite to that in the UK.

Concerning symptoms and diseases, almost all show worse health evaluation, although some symptoms and diseases raise health evaluation in significance, such as failing memory, the sniffles, toothache, dental problems, wounds, hyperlipidemia, hypertension, allergic rhinitis, tooth decay, oral problems, and stiff shoulder. In the UK and USA studies, there is no such a counter-intuitive case. Three reasons can be offered in explanation.

Firstly, information of symptoms and sickness in the Japanese data set is more detailed than in the others. If a kind of symptom or sickness is typical at an earlier stage, or typically has co-morbidity with the others, its effect would raise health evaluation.

Secondly, as this survey is conducted for the household member as explained above, those who suffered a certain symptom or sickness would feel better than an inpatient. Hence the health evaluation in this survey is contaminated by such a severe selection, it does not reflect the whole impact of these symptoms and diseases. Thirdly, maybe the most important point is that the reference group that is used by the respondents when they evaluate their health may be falsely imagined. That is, the word "the same age group" is missing in the survey, though it is included in the others. Thus they may compare the current situation with the situation when they were admitted to hospital. Currently they are discharged and enjoying better health, even though they have not recovered completely. In this case, biased sampling excluding inpatients causes counter-intuitive results.

5.3 The Function Threshold Model

Though Groot [4] cannot find significant symptoms or diseases consistently across all threshold functions, Tables 3 indicates that there are many consistently significant variables such as marital status, bleary eyes, the sniffles, retching, appetite loss, stiff shoulder(s), back pain, paramnesia/merrorhalgia, hypertension, other circulatory problems, and gastritis/duadentis. Moreover the coefficients for toothache, oral problems, difficulty in chewing, fractures, wounds, and injuries are consistently negative but insignificant, and thus these symptoms or diseases raise the criterion for good health.

5.4 The Model with Economic Variables

In general, economic situations other than pure health conditions also may affect health-related QOL, but the concept excludes such a non-health condition. Therefore, by estimating it using economic variables, we can control and eliminate the effect of economic conditions and thus measure the pure health related QOL. If not, the estimated QOL is biased by the economic situation.

Table 4 shows the results. Though it shows that aging significantly reduces subjective health evaluation, many variables are almost the same as the number in Table 2. On the other hand, in the function threshold model summarized in Table 5, the number of significant variables in the threshold function decreases. Only bleary eyes, the sniffles, retching, back pain, broken bones and sprain, hypertension, and other circulatory problems are consistently significant in the threshold function.

5.5 Restrictive Estimation Comparing the UK and USA

Since the data set in Japan is more detailed than for the UK or the USA, as mentioned above comparison among countries may be affected. To control for this problem, a restrictive model that includes only variables comparable with the UK and USA study as explanatory variables is performed in this subsection.

In the constant threshold model summarized in Table 6, cataracts, hypertension, allergic rhinitis, atopic dermatitis, and contact dermatitis remain as counter-intuitive results in which these diseases raise subjective health evaluation. On the other hand, the function threshold model in Table 7 shares results with the non-restrictive model, which means that there are many consistently significant variables in the threshold function, except for the sniffles.

To sum up, such a restriction does not have much effect and thus the more detailed information in Japan does not cause counter-intuitive phenomena.

6 Estimation Results for QOL

Table 8 summarizes the QOL. In the case of diabetes, we observe 0.86 in the UK, 0.66 in the USA, and 0.954 in Japan. For hypertension, while it is 0.86 in USA, it is 1.004 in Japan.

Conversely, the QOL values for difficulty in seeing are 0.93, 0.92 and 0.985, and difficulty in hearing are 0.93, 0.97 and 0.996 in USA, UK and Japan, respectively. In some symptoms or diseases, the QOL among countries are almost the same. However, for most symptoms or diseases, QOLs are higher in Japan than in UK and USA.

Next, Table 9 shows QOL in the function threshold model. For diabetes, we observe 0.85 for the UK and 0.942 for Japan, and for difficulty of seeing, 0.94 for the UK and 0.979 for Japan. Hence, even in the function threshold model, the QOL in Japan is higher than in UK and USA.

Estimation results with economic variables can isolate pure QOL which is not affected by such economic conditions, but these are not considered in the existing literature. The QOL in the constant threshold model is shown in Table 10, and the function threshold model in Table 11. Though the number of significant coefficients decreases, QOL is not so much affected by introducing economic variables; for instance in the case of diabetes, it is

0.955 in both models.

QOL_{HO} , our original QOL definition which is to be $[0,1]$ by definition, is also shown in the tables. In comparison with Cutler and Richardson [3] and Groot [4], $QOL_{CR,G}^f$ s are adjusted for the loss of QOL by certain of symptoms or diseases, $1 - QOL_{CR,G}^f$. Overall, QOL_{HO} is smaller than $1 - QOL_{CR,G}^f$. For instance, in the case of diabetes, while $1 - QOL_{CR,G}^f$ is 0.059, QOL_{HO} is only 0.015. In the case of hypertension, $0.032(1 - QOL_{CR,G}^f)$ is compared to $0.009(QOL_{HO})$. In other words, this discrepancy indicates the possibility of systematic overestimation of damage to QOL in the existing literature because of appropriateness of QOL_{HO} as discussed above.

7 Concluding Remarks

This paper applies the same procedure as in the existing literature to Japan, and then improves upon it. Firstly, while the previous studies define the domain of QOL in an ad hoc manner, i.e. excluding "excellent" or "very poor" respondents, this paper suggests a more rigorous alternative measure. Secondly, heterogeneity among individuals, which is inevitable in micro-data, is accounted for in the estimation. Thirdly, economic variables such as income or job status that are considered to affect subjective health status are also accounted for. The estimation results show that in the same model as the previous ones, similar tendencies are found, but coefficients are smaller for many symptoms and diseases. Economic variables help to clarify the effect of symptoms or diseases on subjective health evaluation. The damage of QOL by symptoms and diseases defined in this paper is smaller for most symptoms and diseases, and thus the measures in the previous research are likely to overestimate it and may be inappropriate.

Finally, we make suggestions for further research. As emphasized above, the most important difference between Japan and others appears to be the lack of the phrase "comparison with the same age group." This lack seems to contaminate the result heavily. To overcome

this problem, a survey including such a phrase should be performed. Moreover, longer macro QOLs should be calculated for evaluating health care.
